Anaplasma phagocytophilum

Disease Agent:
- *Anaplasma phagocytophilum* (formerly referred to as *A. phagocytophila*, *Ehrlichia phagocytophila* and *Ehrlichia* spp)

Disease Agent Characteristics:
- Obligate, intracellular, Gram-negative bacterium with tropism for neutrophils
- Order: Rickettsiales; Family: Anaplasmataceae
- Size: 0.5-0.8 μm × 1.2-3 μm
- Nucleic acid: A circular DNA of about 1500 kb
- Physicochemical properties: The rickettsiae are susceptible to 1% sodium hypochlorite, 70% ethanol, glutaraldehyde, formaldehyde, and quaternary ammonium disinfectants and are sensitive to moist heat (121°C for at least 15 min) and dry heat (160-170°C) for at least 1 hour.

Disease Name:
- Human granulocytic anaplasmosis (HGA); previously known as human granulocytic ehrlichiosis (HGE)

Priority Level:
- Scientific/Epidemiologic evidence regarding blood safety: Moderate
- Public perception and/or regulatory concern regarding blood safety: Low
- Public concern regarding disease agent: Low/moderate in focal endemic areas

Background:
- Emergent; first described in 1994 as the causative agent of HGE (now HGA). HGA became a reportable disease in 1999. The majority of cases reported to CDC (90%) come from New York, Connecticut, New Jersey, Rhode Island, Minnesota and Wisconsin. Incidence of reported cases has increased almost 5-fold from 2000 to 2010 probably due to increased awareness resulting in better diagnosis and surveillance, and/or spread of infected ticks.

Common Human Exposure Routes:
- Tick-borne zoonosis; humans are accidental/incidental hosts.
- Transmitted by the same tick vectors as those that transmit Lyme disease and babesiosis: *Ixodes scapularis* ticks in the Northeast and upper Midwest (also known as the deer tick or the black-legged tick); incidence peaks synchronized to tick seasons in affected areas. The majority of cases occur during the summer months with a peak observed during June/July.
- *I. pacificus* (western black-legged tick) transmits the infection in the western US, while *I. ricinus* and *I. persulcatus* are the principal vectors in Europe and Asia, respectively.
- Reports of transfusion transmission increasing

Likelihood of Secondary Transmission:
- None documented

At-Risk Populations:
- Individuals at enhanced risk for exposure to infected ticks through outdoor activity, including those involved in hiking, gardening, clearing brush, etc.
- The frequency of reported cases is higher among males and anyone over 40 years of age.
- A compromised immune system due to cancer treatments, advanced HIV infection, prior organ transplants, or immune suppression may increase the risk of severe outcome.

Vector and Reservoir Involved:
- Ticks of genus *Ixodes* (*I. scapularis*, *I. pacificus*, *I. ricinus*, *I. persulcatus*)
- The tick nymph is primarily responsible for transmission of Lyme disease, babesiosis, and HGA, although adult stages also can transmit infection. Because of its small size, the bite may not be noticed and consequently the tick may not be removed before disease transmission occurs.
- White-footed mice (*Peromyscus leucopus*), raccoons (*Procyon lotor*), gray squirrels (*Sciurus carolinensis*), Northern short-tailed shrews (*Blarina brevicauda*), Eastern chipmunks (*Tamias striatus*), and several other small mammals have demonstrated competency as reservoir hosts in the US.
- White-tailed deer (*Odocoileus virginianus*) harbor a similar strain of *A. phagocytophilum* not associated with human infections; therefore, they are not considered competent reservoirs for strains that cause HGA.

Blood Phase:
- The bacteremia lasts for days to a few weeks after the occurrence of symptoms.
- The duration and frequency of asymptomatic bacteremia have not been documented.

Survival/Persistence in Blood Products:
- Viable organisms have been recovered from anticoagulated, refrigerated whole blood from infected patients for 2 weeks and transmitted by transfusion in animal models (sheep) after 13 days. In a single case (abstract), RBCs stored for 30 days from a seropositive/PCR-negative donor transmitted the organism to a recipient who at diagnosis was seroconverting, PCR positive, and febrile. Among fully published cases, *A. phagocytophilum* survived for 8-15 days in packed RBCs.

Transmission by Blood Transfusion:
- Eight cases have been reported; seven in the US and one in Europe. Specific details of these cases are presented in the attached Table. Key elements follow below.
  - Cases are being recognized more frequently; seven of eight cases reported since 2007.
Patients ranged in age from 36 to 85 years of age, but majority (n = 6) were over 50 years of age. Gender distribution equally split; 4 female and 4 male.

HGA generally suspected by identifying morulae (microcolonies of Anaplasma) on blood smear; confirmation by PCR and/or seroconversion

Patients treated with doxycycline demonstrated rapid improvement and resolution of infection.

Implicated donors ranged in age from 42 to 81 years of age and most reported risk factors for exposure to A. phagocytophilum including tick bites, time spent in an endemic area, or febrile illness prior to donation. For most cases, index donation was PCR positive.

Leukoreduced, as well as non-leukoreduced products implicated in transmission. Products ranged in age from 5 to 30 days at the time of transfusion. Most recent case implicated a leukoreduced apheresis platelet product.

A cluster of cases of apparent human-to-human transmission of A. phagocytophilum infection (and the first report of HGA in China) associated with blood contact was reported in 2008. The infection was not confirmed by blood smear or culture in the index patient, but A. phagocytophilum DNA was amplified from and sequenced from the patient who had been bitten by a tick, and nine family members or healthcare workers who had been in close contact. All nine reported contact with the patient's blood; seven had contact with respiratory secretions. The index patient died before seroconversion, but all nine contacts seroconverted.

Cases/Frequency in Population:

- Seroprevalence:
  - Blood donors: 11.3% of Westchester County, New York donors, 0.5% of Wisconsin donors, and 3.5% of Connecticut donors had antibodies to A. phagocytophilum.
  - Residents: 0.4% in northern California, 3.4% in New York, 14.9% in northwestern Wisconsin had antibodies to A. phagocytophilum.

- Incidence: During 2000-2010, the reported annual US incidence increased from 1.4 to 6.1 cases per million population. In 2010, 1,716 cases were reported to the CDC. The number of infected individuals and clinical cases are likely much higher due to underreporting and lack of recognition of this often nonspecific infection.

Incubation Period:

- 7-10 days from tick bite to bacteremia and acute symptoms

Likelihood of Clinical Disease:

- Low to moderate
- Males outnumber females by a 2:1 ratio
- Immunocompromised and elderly patients are at greater risk to develop more severe manifestations of disease.

Primary Disease Symptoms:

- Nonspecific febrile illness characterized by high-grade fever (>39°C), rigors, generalized myalgias, severe headache, and malaise often accompanied by thrombocytopenia, leukopenia, and elevated liver transaminases occurs approximately 5-21 days after a bite from an infected tick.
- Anorexia, arthralgias, nausea, nonproductive cough, and rash are sometimes present.
- Median duration of illness is 9 days (1-60 days).

Severity of Clinical Disease:

- Generally not severe
- Severe cases are characterized by prolonged fever, acute renal failure, gastrointestinal bleeding, septic shock-like illness, rhabdomyolysis, respiratory insufficiency, and secondary opportunistic infections.

Mortality:

- 1% mortality

Chronic Carriage:

- Not documented in humans. Of interest, a chronic, subclinical infection of almost one year was reported in dogs inoculated with a human isolate from New York.

Treatment Available/Efficacious:

- Tetracyclines (e.g., doxycycline) are therapeutically effective.
  - Rifampin may be effective based on limited data in those who cannot take tetracyclines (e.g. pregnant women or those with allergy).

Agent-Specific Screening Question(s):

- No specific question is in use.
- Not indicated at this time because relatively few cases of transfusion transmission have been reported.
- No sensitive or specific question is feasible. In endemic areas, a question on exposure to tick bites has been shown to be ineffective in distinguishing Babesia-infected from Babesia-uninfected donors. This question probably also lacks sensitivity and specificity for A. phagocytophilum.

Laboratory Test(s) Available:

- No FDA-licensed blood donor screening test exists.
- Options for laboratory testing include blood smear microscopy, cell culture, IFA, EIA, and NAT
  - During the first week of infection, examination of peripheral blood smears may reveal morulae in the cytoplasm of white blood cells in 25-75% of patients. Morulae are most frequently observed in granulocytes.
  - Specialized cell culture techniques can be used to amplify the infection and observe infected cells. Sensitivity is > 55% in the first week, falling to 33% during week two.
ELISA is considered the gold standard serologic test. A four-fold rise in IgG antibody levels to *A. phagocytophilum* antigen is considered diagnostic for a recent infection. Sensitivity ranges from 22-44% in the first week after onset to > 95% at 3 weeks and beyond.

PCR detection primarily during first week of infection (67-90%); thereafter sensitivity rapidly declines, particularly after administration of appropriate antibiotics.

**Currently Recommended Donor Deferral Period:**

- No FDA Guidance or AABB Standard exists.
- In an individual who receives treatment, prudent practice would be to defer donor until signs and symptoms are gone and treatment is complete.
- Based on the natural history of infection, it may be prudent to defer an untreated individual for a minimum of 90 days (30 days beyond the longest duration of illness).

**Impact on Blood Availability:**

- Agent-specific screening question(s): Not applicable
- Laboratory test(s) available: Not applicable; serologic testing, if implemented in the future, could result in a deferral rate of 3-5% in selected collection areas.

**Impact on Blood Safety:**

- Agent-specific screening question(s): Not applicable
- Laboratory test(s) available: Not applicable

**Leukoreduction Efficacy:**

- Preliminary studies indicate that leukoreduction reduces, but does not eliminate transmission risk associated with *A. phagocytophilum*. Recent transfusion cases implicating leukoreduced products support this observation.

**Pathogen Reduction Efficacy for Plasma Derivatives:**

- Not expected to be transmitted by plasma derivatives

**Other Prevention Measures:**

- Tick avoidance measures (e.g., long pants, long sleeves, insect repellant)
- Riboflavin/Light has been effective in inactivating *Orientia tsutsugamushi*, a similar obligate intracellular pathogen.
